Abstract: Worldwide, large studies have shown that the menopause is mainly associated with substantial changes in body composition that result in an increase in waist circumference, fat accumulation and specially weight gain. This overweight could be exacerbated by fat intake. Thus, this study was planned to evaluate the impact of the consumption of olive and argane oils on anthropometric profile and body composition of postmenopausal women. The nutritional intervention was conducted over a period of eight weeks, involving daily consumption of 25 mL of argane oil or olive oil in 151 postmenopausal women (55.49 ± 6.18 years old). The anthropometric profile (weight, height and body mass index (BMI)) and body composition (fat mass (FM) and lean mass (LM)) were determined at 0 week (baseline), and after the 4th and 8th weeks of nutritional intervention. Results clearly demonstrated that argane oil or olive oil consumption did not affect the anthropometric parameters and the body composition of postmenopausal women. Thus, argane and/or olive oils' regular diet does not lead to weight gain, and postmenopausal women could benefit from their impact on health for a better quality of life and to overcome all menopause associated problems. A longer period of nutritional intervention is required to confirm the trend down that was recorded.

Key words: Olive oil, argane oil, anthropometry, postmenopausal women.

1. Introduction

Menopause is a normal physiological process that marks the end of the fertile period for women, the cessation of ovarian function and arrest of secretion of female hormones, estrogen and progesterone. It naturally occurs one year after the end of menstruation and can be artificially induced after surgical removal of ovaries (castration).

Depending on the physiological status of women, menopause may be associated with a number of events, including hot flashes and substantial changes in body composition that result in an increase in waist circumference, fat accumulation and specially weight gain [1, 2]. Indeed, during menopause, the decreased estrogen secretion results in a spontaneous increase in fat mass (FM) and decrease in muscle mass [3]. In addition, lower level of progesterone and estrogen production affects the thyroid activities, resulting in a slower metabolism and usually accompanied by

weight gain [4].

In Morocco, like most Mediterranean countries, the diet is rich in fat intake, which is an average of 19.36 kg/person/year. Household surveys in 2001, conducted by the Department of Statistics showed that consumption of oils in general is averaged with 16.1 kg/person/year (Department of Statistics, Kingdom of Morocco, 1970 to 2001). In addition, lipids represent on averagely 38.5% of energy intake of men and 39.6% of women [5].

It is widely accepted that the impact of lipid intake on health is closely linked to their content of saturated and unsaturated fatty acids [6, 7]. Excessive consumption of unsaturated or trans fatty acids, appears to be an increased risk factor, in a convincing level, to develop overweight associated diseases [6, 7].

Most cross-sectional studies showed a positive correlation between the fat percentage in the diet and the obesity. Excessive fat intake can promote an imbalance between energy intake and energy expenditure, which could increase the risk of obesity [8]. Moreover, the association between weight gain inherent to menopause [1] and the one due to a diet with a high fat intake [8], is bad for menopausal women and can lead to an increased risk of cardiovascular disease, breast cancer and even of neurodegenerative diseases [9].

In Morocco, argane and olive oils play an important role in the national economy. This country is one of the main producers/suppliers of these oils worldwide. Moroccan people are also high consumers of argane and olive oils; these two oils are the basis of the diet in many parts of the country.

Olive and argane oils are products of great importance and their nutritional value has been recognized internationally. Over the years, the diet based on consumption of olive and/or argane oils became widely associated with better health and protection against cardiovascular diseases and cancers of the colon, breast and skin [10]. The beneficial effect is attributed to a favorable fatty acid profile and

the presence of some minor components that are responsible for flavors and tastes of these oils [11, 12]. In addition, olive and argane oils are traditionally used in Morocco for ointments skin care or soaps manufacture. More components of those two oils are a source of antioxidants and components with anti-inflammatory activity. Argane oil contains 80% of saturated fatty acids: palmitic acid, stearic acid and linoleic, which are known for their preventive role against cardiovascular diseases [13-15]. Schottenol and spinasterol are rarely found in vegetable oils and are characteristic of argane oil; these two molecules have probable anti-carcinogenic properties [16, 17].

Olive oil has great beneficial health properties. Large studies have been conducted and have reported that consumption of olive oil reduces the risk of cardiovascular diseases, due to the presence of vitamin A (3-30 mg/kg of provitamin A carotene), vitamin E (150 mg/kg of α -tocopherol) and mono-unsaturated fatty acids [18]. Moreover, olive oil is rich on oleic acid, whose content may vary from 55% to 83%. Finally, the tocopherol wealth of argane and olive oils gives them a strong antioxidant effect [19].

During recent decades, women have acquired a high awareness that weight gain during menopause is risk factor for developing various diseases, particularly cardiovascular disease [3].

To assess whether postmenopausal women can still enjoy the benefits of argane and olive oils, and to our knowledge that no study has been conducted on the impact of the consumption of these oils on the anthropometric profile of a population of postmenopausal women, the authors have planned to evaluate the impact of the consumption of these oils on anthropometric profile and body composition of postmenopausal women.

2. Materials and Methods

2.1 Subjects and Recruitment

The study was conducted on a sample of 151 postmenopausal women aged over 40 years old.

Menopausal status was confirmed by blood analysis of follicle stimulating hormone (FSH), which must be less than 40 IU/L [20]. Women with diabetes, cardiovascular disease, hypo- or hyperthyroidism or digestive problems involving lipid malabsorption, were excluded from the study. The study was performed on consenting women after approval by the ethics committee of the Faculty of Medicine and Pharmacy of Rabat, Morocco.

2.2 Oils

Argane oil was purchased from the Targante cooperative (Arganati). Olive oil was kindly provided by the company Oued Souss.

2.3 Protocol

The study was conducted between October 2008 and July 2010. The population was randomly divided into two groups: group I (77 women) who consumed argane oil and group II (74 women) who consumed olive oil.

The nutritional intervention was preceded by a stabilization period of two weeks, in which all the participants consumed 25 g of a non-hydrogenated vegetable margarine. During this period, the participating women have consumed neither olive oil nor the argane oil.

For the eight weeks of nutritional intervention, group I received 25 mL of argane oil/d and group II 25 mL of olive oil/d. The measurements were taken at the end of stabilization period “baseline” (T_0), after four weeks (T_1) and after eight weeks (T_2) of intervention.

The caloric intake of oil was calculated on basis of the oil density (0.92 kg/L for argane oil as well as olive oil) and energy from fat intake (9 kcal/g). Also, the energy supply of argane oil and olive oil are both 207 kcal.

2.4 Anthropometric Measurements

Anthropometry was measured according to Refs. [21, 22]. The body weight of participating women,

dressed in light suits, was measured with a mechanical scale (150 ± 0.1 kg, Seca 750, Germany). Standing height was taken barefoot, using a stadiometer (200 ± 0.1 cm, Seca 217, Germany). The body mass index (BMI, kg/m^2) was calculated based on Eq. (1) [23]:

$$\text{BMI (kg/m}^2\text{)} = \text{weight/}(\text{height standing})^2 \quad (1)$$

Waist and hip circumference were measured using a centimeter tape (220 ± 0.1 cm).

2.5 Skinfolds

All measurements were taken on the right side of the body. The selected sites are: triceps, biceps, supra-iliac and subscapular. Triceps fold is located in midway between the posterior surface of the arm, between the edge of the acromion and the olecranon, in the direction of the triceps length, held vertically with the arm. The biceps crease was measured using half of the arm as benchmarks, it is located on the front of the arm just above the center of the cubital fossa, the same level as the fold of the triceps. The skin is pinched in the direction of the length of the biceps, mid-distance, facing the front of the arm, the participant holding his bent arm. Subscapularis fold is just below the tip of the inferior angle of the scapula, is formed and oriented upwards and inwards at an angle of about 45° with the vertical. The supra-iliac fold is just above the iliac crest in the mid-axillary line, vertical anterior edge of the armpit to the iliac crest. When measuring these four folds, the fold was kept clamped firmly between the thumb and forefinger, and slightly detached from the underlying tissue before applying the compass to measure. Folds determination was performed with a specially calibrated clip (adiposity-meter) to measure the fold thickness without overwriting the subcutaneous adipose tissue (the compass of Harpenden).

2.6 FM

Calculation of FM is done using the equation of Siri [23] as Eq. (2):

$$\text{FM (\%)} = [(4.95/\text{body density}) - 4.51] \times 100 \quad (2)$$

To calculate body density (d), the following Eq. (3) was used:

$$d = [c - m \times \log(\text{sum of skinfolds})] \quad (3)$$

The two constants c and m were determined following the tables of Durnin based on age of participants and the number of skin folds used [23]. The fat was expressed per kg body weight.

2.7 Body Lean Mass (LM)

LM was obtained by subtracting the fat of the total body mass, considering the body as a two-compartment model.

2.8 Statistical Analysis

Data processing and statistical analysis were performed using the software “Statistical Package for the Social Science” (SPSS version 11.0).

3. Results

The average age of the study population is 55.4 ± 6.1 years old. The population has an average size of 1.58 ± 0.28 m, with a minimum of 1.46 m and a maximum of 1.74 m (Table 1).

From T_0 to T_2 , the effect of the consumption of olive or argane oils on the weight of postmenopausal women is reported in Table 2.

The results showed that the nutritional intervention neither based on argane oil (group I) nor olive oil (group II) cause significant changes in the weight of women, respectively, with $P = 0.8068$ and $P = 0.7580$. Consecutively, the BMI remains stable for both oils, with no significant difference (group I $P = 0.9214$ and group II $P = 0.07344$). However, for both groups, trend down could be recorded. This is noted for weight and waist circumference (WC) of postmenopausal women.

Moreover, the nutritional intervention did not exhibit any difference on the WC of participated women, either for the olive group or the argane group.

Body composition of female participants is reported in Table 3. The analysis of body fat in postmenopausal women, calculated from skin folds, showed an average of $40.57\% \pm 4.80\%$. Data analysis showed that the average population has an excess of FM $> 28\%$ for both the group who consumed argane oil (group I) and olive oil (group II). For both groups,

Table 1 General characteristics of the population at T_0 .

Anthropometric characteristics	Group I (T_0)	Group II (T_0)	Total of group I and II
Age (year)	55.5 ± 6.1	55.4 ± 6.1	55.4 ± 6.1
Height (m)	1.58 ± 0.05	1.58 ± 0.06	1.58 ± 0.28
Population size	77	74	151

Table 2 Anthropometric characteristics of the population at T_0 and T_2 .

P means the statistical difference between T_0 and T_2 .

body composition evaluated by free mass and LM, no difference was reported during the intervention period with $P > 0.05$.

4. Discussion

Thus, postmenopausal women seek to take control of weight gain inherent to physiological change, mainly through diets limiting fat intake [3]. Furthermore, it is assumed that the diet has a great influence on the health of women and changes in body composition in postmenopausal women, it could be offset by an appropriate low diet in sugars, but does not prevent regular fat intake [23]. Also, the interest of this study is to see if the daily intake of two virgin oils widely used in Morocco—olive and argane oils, may have an influence on body composition in postmenopausal women.

This study showed that the population is predominantly recruited overweight even obese with a mean BMI of 28 kg/m^2 and an average body fat percentage of 40% of total body composition, with two methods: skinfolds and bioelectrical impedance analysis (BIA). Overall, these parameters are 40% higher than international standards [24]. In USA, the increase in FM in postmenopausal women, due to hormonal changes, can reach 26% of premenopausal FM [24, 25].

After stabilization, each woman has a specific physiology lipid status in relation to the quality of fat intake defined during this period. Therefore, the daily caloric intake remained constant and only the qualitative reports of saturated or unsaturated fatty acid were changed.

Through this study, the results showed that nutritional intervention based on argane oil or olive oil, has no significant effect on anthropometric profile of postmenopausal women, evaluated by measuring the weight, waist circumference and BMI. These results are consistent with the study conducted by Derouiche et al. [26], who reported that in adult men within a controlled environment, the daily consumption of

argane oil has no effect on the anthropometric status [26, 27]. Experiments *in vivo* on animal models showed that nutritional intervention based on dietary argane oil led to a significant decrease of body weight after six weeks, which was accompanied by reduction of blood lipoproteins, total cholesterol, low density lipoprotein (LDL)-cholesterol and triglycerides [28]. The beneficial effect of argane oil on human health was also reported by Ould-Mohamedou et al. [29], showing a great impact on lipid profile and LDL susceptibility to lipid peroxidation in both healthy subjects and dyslipidemic patients.

Regarding olive oil, large studies have been interested on the beneficial effect of olive oil consumption on human health. Even the impact of olive oil consumption has been largely studied, the effect on anthropometric parameters and body mass composition is still limited. Interestingly, a two months nutritional intervention on postmenopausal women showed that conjugated linoleic acids significantly reduced body weight and similar tendency in total and lower-body FM [30]. Experiments in animal models have shown that a controlled diet including olive oil with or without polyphenols causes no weight gain during the intervention period [31]. In addition, a similar study in a population of young women showed that after four weeks of nutritional intervention, a diet including olive oil shows no change in body weight in this population [32]. The beneficial impact of olive oil could be mainly due to the presence of oleuropein derivatives. Indeed, many studies strengthen the hypothesis that oleuropein derivatives play a major role in the health benefits of olive oil [33]. Oleuropein have several pharmacological properties, including anti-oxidant [33, 34] and anti-atherogenic [12]; and for these reasons, it is commercially available as a dietary supplement in the Mediterranean countries. In addition, it has been shown that oleuropein has cardio-protective effect against acute cardiovascular toxicity of adriamycin [35] and also an anti-ischemic

and hypolipidemic effect [36].

Despite the relatively small numbers of women involved in this study and the relatively short duration of the intervention, the results clearly show that the caloric intake of argane and olive oils from the order of 207 kcal/d does not cause weight gain in postmenopausal women. However, it could not be assumed that the weight stagnation is not a consequence of energy expenditure. Unfortunately, the authors did not assess physical activity during the intervention, but they have emphatically recommended to all participant women to keep their lifestyles.

This regular and adequate fat intake is essential for proper functioning of the human body. It provides in part the energy for cellular metabolism, helps regulate body temperature as well as hormone synthesis, provides essential fatty acids and allows the absorption of micronutrients such as vitamins A, D, E and K. To confirm the trend down that was recorded, probably a longer period of nutritional intervention is required.

5. Conclusions

In conclusion, both argane and olive oils show a positive impact on health, and the economic valuation of the argane and olive trees through its products is a way to restart sustainable integrated rural forestry. Indeed, previous research has shown that the argane tree is a future for certain arid areas. Thus, strengthening the scientific research is the key to success for any policy development and wealth creation and a key support to economic development.

The argane tree is a tree which risks disappearing, due to desertification and that goats eat young ones or people use it as firewood. Therefore, it becomes imperative to keep this universal heritage as sustainable resources. Showing the positive impact of the argane oil on human health adds more value to it and help to mobilize to safeguard this tree.

This paper shows that both argane and/or olive oils' regular diet, does not lead to weight gain, and

postmenopausal women will benefit from their beneficial impact on health for a better quality of life and to overcome all menopause associated problems.
